# 1    **Abstract**

2                Studies of neuronal network emergence during sensory processing and motor  
3    control are greatly promoted by technologies that allow us to simultaneously record the  
4    membrane potential dynamics of a large population of neurons in single cell resolution.  
5    To achieve whole-brain recording with the ability to detect both small synaptic potentials  
6    and action potentials, we developed a voltage-sensitive dye (VSD) imaging technique  
7    based on a double-sided microscope that can image two sides of a nervous system  
8    simultaneously. We applied this system to the segmental ganglia of the medicinal leech.  
9    Double-sided VSD imaging enabled simultaneous recording of membrane potential  
10    events from almost all of the identifiable neurons. Using data obtained from double-sided  
11    VSD imaging we analyzed neuronal dynamics in both sensory processing and generation  
12    of behavior and constructed functional maps for identification of neurons contributing to  
13    these processes.

# 1     **Introduction**

2             One of the principal goals in neuroscience is to clarify how neuronal circuits  
3     process sensory information and control behavior. Sensory information and behavioral  
4     states are represented as dynamic activity patterns of neuronal populations in large  
5     neuronal networks. To clarify the neuronal mechanisms underlying sensory processing  
6     and behavioral generation, it is necessary to determine which neurons are involved in  
7     functionally relevant neuronal dynamics and how those neuronal components interact  
8     with each other within the larger network. Technological advances in neuroimaging have  
9     enabled brain-wide recording of neuronal activity with sufficiently fine spatial resolution  
10    to identify individual neurons within a population<sup>1</sup>. Researchers can perform  
11    pan-neuronal Ca<sup>2+</sup> imaging in selected animals with small size nervous systems,  
12    including larval zebrafish<sup>1</sup> and *C. elegans*<sup>2-4</sup>.

13            Although Ca<sup>2+</sup> imaging is a convenient tool for detecting neuronal activity, it is  
14    limited to intracellular events that are associated with a change in Ca<sup>2+</sup> concentration.  
15    Thus, Ca<sup>2+</sup> imaging measures neither subthreshold depolarizing nor hyperpolarizing  
16    synaptic events. Accordingly, it is difficult to observe synaptic integration processes  
17    using Ca<sup>2+</sup> indicators. In contrast, voltage sensitive dyes (VSDs) can detect both action  
18    potentials and sub-threshold excitatory and inhibitory synaptic potentials. Voltage  
19    sensors have enabled neuroscientists to examine ethologically relevant neuronal  
20    dynamics and to functionally map parts of the nervous systems of sea slugs<sup>5-7</sup> and the

1 medicinal leech *Hirudo verbana*<sup>8-10</sup>. The segmental ganglion of the leech is particularly  
2 well suited for comprehensive recording using VSD imaging for two reasons: It consists  
3 of only about 400 identifiable neurons<sup>11</sup> arranged in a well-preserved geometry in a  
4 single spherical shell surrounding a central neuropil, and it functions as a basic unit of  
5 sensory processing and control of several behaviors<sup>12</sup>. In the leech segmental ganglion,  
6 multiple neuronal circuits responsible for reflexive and voluntary locomotor behaviors  
7 have already been characterized by electrophysiology and VSD imaging<sup>8-10, 12</sup>. However,  
8 existing technology only allowed imaging one side of a ganglion at a time, and hence  
9 captured the activity of at most half of the full ensemble of neurons: they could record  
10 from, at most, approximately 15% of all 6000 neurons in a pedal ganglion of *Aplysia*, and  
11 fewer than 50% of all 400 neurons in a leech segmental ganglion. In addition, VSDs  
12 applied in these previous studies had a disadvantage either on its sensitivity or its  
13 response speed: electrochromic dyes used in sea slugs do not possess enough sensitivity  
14 to detect subthreshold potentials<sup>5, 6</sup> and FRET-based dye previously used in the leech has  
15 a non-negligible delay between optical signal and actual voltage change<sup>8, 9</sup>.

16 To overcome these limitations, we developed a double-sided microscope for  
17 VSD imaging, consisting of precisely aligned upright and inverted fluorescent  
18 microscopes, and imaged voltage changes from the neuronal membrane stained by a  
19 highly-sensitive, fast VSD<sup>13</sup>. This microscope enabled us to record from all cell bodies of  
20 a leech ganglion regardless of their location, and allowed us, for the first time, to directly  
21 analyze functional relationships between neurons located on opposite surfaces. We

combined this double-sided neuronal imaging system with simultaneous electrophysiological recording and stimulation, which allowed us to monitor motor outputs, to verify agreement of VSD signals with actual membrane potentials, and to activate or inhibit selected target cells by injecting current.

To demonstrate the utility of the newly developed VSD imaging method, we addressed the following two questions. (1) How are individual identifiable neurons that exhibit higher discriminability for the different sensory stimuli distributed across different surfaces of the ganglion? (2) To what extent are neural circuit components unique or shared between different behaviors?

## Results

### *VSD imaging using double-sided microscopy system*

Double-sided VSD imaging requires simultaneously focusing two fluorescent microscopes. We achieved this by mounting the fluorescence train of an Olympus BX upright microscope with a custom focus rack on top of the body of an Olympus IX inverted microscope. Both microscopes were equipped with 20x objectives. An optically stabilized high-power LED<sup>14</sup> provided excitation light through the top objective, which operated in epifluorescence mode. The top objective also functioned as a condenser lens for imaging with the bottom objective, which thus operated in transfluorescence mode (Fig. 1a). Because of the high NA of the top objective, inhomogeneities in the imaged

1 tissue did not cause substantive deviations from uniform illumination of the bottom focal  
2 plane.

3 The two microscopes were first coarsely aligned (to within about 200  $\mu\text{m}$ ) by  
4 moving the upright microscope's body and its objective turret, after which  
5 micro-alignment was achieved by fine-tuning the position of the upright microscope's  
6 objectives in their turret. We used highly sensitive CCD cameras (Photometrics  
7 QuantEM 512SC) to image neuronal activity with single cell resolution throughout the  
8 ganglion (Fig. 1b). We suppressed mechanical vibration noise by replacing the internal  
9 fans of the CCD cameras with external blowers. Photon noise was not substantially  
10 different between the top and the bottom image (Top:  $72 \pm 3$  ppm; Bottom:  $65 \pm 3$  ppm  
11 (mean  $\pm$  SEM over 10 areas size-matched to typical cells).

12 We imaged neural activity with a new-generation voltage sensitive dye,  
13 VF2.1(OMe).H<sup>13</sup>, which is sensitive enough to record subthreshold events and fast  
14 enough to detect action potentials with accurate timing. The dye was loaded into somatic  
15 membranes on both aspects of a ganglion by bath application and a perfusion pump for  
16 targeted delivery<sup>8</sup>. In leech ganglia, the sensitivity reached  $2.7\% \pm 0.3\%$  (mean  $\pm$  SD  
17 across five ganglia in two leeches) at resting potential (-50 mV) (Supplementary Fig.1).  
18 Microscopic motion artifacts can have outsized effects on VSD signals compared to Ca<sup>2+</sup>  
19 signals because of the limited relative change in fluorescence of VSDs and their location  
20 in the cell membrane. Accordingly, we applied a custom motion correction algorithm to  
21 all imaging data (Supplementary Fig.2 & Materials and Methods). Bleaching artifacts in

the optical signals were corrected using locally fitted cubic polynomials<sup>15</sup> (Supplementary Fig.3) and global fluctuations were subtracted away<sup>16</sup> (Materials and Methods). The voltage sensor faithfully detected various types of membrane potential change, including action potentials, excitatory and inhibitory postsynaptic potentials, and rhythmic oscillation during fictive behaviors (Fig. 1d).

### *Panneuronal VSD imaging and functional mapping based on coherence analysis*

We established a mapping between cells seen in the fluorescent images (Fig. 1b) and identified neurons on a canonical map (Fig. 1c) using a semi-automated procedure in a custom user interface (Materials and Methods). One of the major advantages of VSDs is that recorded traces can be directly compared to intracellular voltage recordings. This allowed us to identify selected cells in our recordings by comparing our data to previously published intracellular activity of those neurons in the same behaviors.

Optically recorded signals simultaneously recorded from both sides of the ganglion closely matched typical patterns of fictive behaviors that have been previously well characterized by electrophysiology and single-sided VSD imaging<sup>9,12</sup>. We first focused on fictive swimming, which we induced by electrically stimulating a DP nerve root of a posterior ganglion<sup>9</sup> (typically, M13). We then imaged ganglion M10 with our double-sided microscope and simultaneously recorded intracellularly from selected cells

1 (Fig. 2a). Rhythmic activity associated with swimming was readily observed, and we  
 2 determined which cells were involved in this rhythm by calculating the phase and  
 3 magnitude of coherence<sup>9</sup> for each cell at the frequency with the greatest spectral power in  
 4 the rhythm (Fig. 2b, c). The optical signal of dorsal inhibitor motor neuron DI-1 exhibits a  
 5 well-understood swimming oscillation and was used as the phase reference for other cells.  
 6 Using the VF2.1(OMe).H dye, we were able to confirm the oscillatory behavior of  
 7 neurons previously studied using an earlier-generation dye<sup>9</sup>. In addition, we were able to  
 8 detect weaker oscillations in many other neurons on both sides of the ganglion.

9           Results from coherence analysis obtained from doubly desheathed ganglia  
 10 imaged using either camera in our double-sided microscope closely matched results from  
 11 conventional single-sided imaging, as evidenced by the consistency of the coherence  
 12 maps computed from either method (Fig. 2b and Supplementary Fig.4). The measured  
 13 amplitudes of swim oscillations in motor neuron DI-1, the noise levels in those recordings,  
 14 and the coherence between bilateral homologues of DI-1 were also indistinguishable  
 15 between single-sided and double-sided imaging experiments (Supplementary Fig.4),  
 16 indicating that double-sided imaging does not entail any compromises from an imaging  
 17 quality perspective.

18

# 1    *Encoding of stimulus identity by individual neurons*

2            We used double-sided VSD imaging to record the activity of all neurons in  
3    isolated single ganglia during a fictive reflexive behavior known as local bending, a  
4    withdrawal response to tactile stimulation in which the leech bends its body away from  
5    the stimulated location<sup>12</sup>. Local bending can be induced readily in isolated single ganglia  
6    by stimulating one of four pressure-sensitive sensory neurons (P cells). Stimulating P  
7    cells causes a combination of excitation and inhibition in identified “local bend  
8    interneurons” (LBIs)<sup>12, 17</sup>. The LBIs synapse onto several motor neurons to produce an  
9    appropriate pattern of contraction and relaxation in the local area of the body wall that  
10   depends on which location (or which P cell) was stimulated<sup>12, 17, 18</sup>.

11           We induced local bending by stimulating the left and right ventral P cells ( $P_V^L$   
12    and  $P_V^R$ ) with trains of depolarizing pulses (20 Hz, 50% duty cycle, 1 s), which reliably  
13    evoked action potentials in those cells (Fig. 3a, b). Stimuli were presented in order of  
14    LRLLR..., for a total of 10 stimuli per P cell. From each of the resulting VSD traces, we  
15    extracted the average fluorescence change ( $\Delta F/F$ ) during the first 0.5 s of the stimulus as  
16    well as during a control phase (1–0.5 s before stimulus onset), both relative to a reference  
17    phase (0.5–0.1 s before stimulus onset; Fig. 3c). Using a leave-one-out procedure, we  
18    calculated for each of the cells how reliably their activity could be used to “predict”  
19    which of the P cells had been stimulated (Fig. 3d). We then established a mapping  
20    between cells in the VSD images and identified neurons on the canonical maps to

1 determine for all identified neurons to what degree their activity encoded stimulus  
2 identity (Fig. 3e).

3 On average across eight experiments,  $113 \pm 11$  (mean  $\pm$  SD) cells on the ventral  
4 surface and  $129 \pm 6$  on the dorsal surface could be mapped to identified neurons (Fig. 3f).  
5 Among those, 28% of ventral cells [ $35 \pm 11$ , mean  $\pm$  SD] and 36% of dorsal cells ( $52 \pm$   
6 18) encoded stimulus identity with prediction success higher than 75% during the first 0.5  
7 s of the stimulus. This included one ventral LBI, all dorsal LBIs, and most motor neurons  
8 (MNs; Fig. 3g). (All other ventral LBIs had prediction success in the range 65%–75%. In  
9 contrast, the average prediction success in the control period was at chance level: 50.9 %  
10  $\pm 1.3\%$  (mean  $\pm$  SEM) for both ventral and dorsal cells.) The other neurons with high  
11 prediction success were AP cells and Leydig cells, as well as cells provisionally identified  
12 as cells 56, 61, 251, and 152 on the ventral surface and cells 9, 10, 22, 28, 107, and 123 on  
13 the dorsal surface.

14

### 15 *Involvement of individual neurons in multiple behaviors*

16 To further establish the utility of double-sided VSD imaging, we set out to  
17 determine to what extent neural circuit components are unique or shared between three  
18 behaviors: local bending, swimming, and crawling. To do so, we evoked the  
19 corresponding fictive behaviors in isolated whole nerve cords using electrical  
20 stimulation<sup>9</sup>. Specifically, local bending was activated by intracellular stimulation of a

1 single  $P_V^L$  or  $P_V^R$ <sup>19</sup>; swimming was elicited by stimulating a DP nerve from either  
 2 ganglion 11, 12, or 13; and crawling was elicited by stimulating tail brain nerve roots.  
 3 Motor patterns of local bending and swimming were confirmed based on extracellular  
 4 recordings of DP nerves or intracellular recording of AE cells<sup>9, 10, 20</sup>. Crawling patterns  
 5 were confirmed based on by simultaneous intracellular recordings from two different  
 6 motor neurons: the AE and CV cells<sup>9</sup>. All three behaviors could be induced in each of six  
 7 animals (Supplementary Videos 1–4).

8 We calculated the phase and magnitude of the coherence of each imaged  
 9 neuron to the stimulus train (0.5 Hz) during local bending; to the optical signal of motor  
 10 neuron DI-1 during swimming; and to the intracellular trace of an AE cell during crawling.  
 11 Results from all behaviors in one animal are shown in Fig. 4a–d and Supplementary  
 12 Videos 1–4. Optical signals from representative cells located on both surfaces confirmed  
 13 stereotyped activity patterns that were highly distinctive for each of the behaviors (Fig.  
 14 4e–h).

15 We established identities of imaged neurons as before. On average over six  
 16 preparations, we were able to assign  $126 \pm 11$  cells on the ventral surface and  $121 \pm 10$  on  
 17 the dorsal surface. This allowed us to construct summary maps showing which neurons  
 18 were consistently involved in which behaviors (Fig. 4j and Materials and Methods).  
 19 Approximately 10% cells were involved in all three behaviors, 33% in two out of the  
 20 three behaviors, and 42% in a single behavior (Fig. 4j). For the remaining 15% of cells,  
 21 involvement in any of the behaviors could not be established.

1           Finally, we calculated a correlation matrix between the recorded activity of  
2   each of the cells, separately during each of the three behaviors, and performed automated  
3   clustering based on these correlations (Fig. 5a). For each of the cells in a recording, we  
4   then calculated what fraction of the cells in the same cluster were located on the ventral or  
5   the dorsal side of the ganglion. We found that during crawling and especially during local  
6   bending, most clusters were largely confined to only one side of the ganglion, whereas  
7   during swimming they more commonly spanned sides (Fig. 5b), which indicates that  
8   swimming involves correlated activity among cells located on both surfaces whereas  
9   local bending largely does not. We quantified this by calculating an “integration  
10   coefficient” (Materials and Methods) which is equal to zero if all clusters are either  
11   wholly on the dorsal or wholly on the ventral side, and equal to one if all clusters are  
12   equally spread between the two sides (Fig. 5c).

13

## 14   **Discussion**

15           We constructed a double-sided microscope that can record fluorescence signals  
16   from two sides of a biological preparation. This technique should be broadly applicable to  
17   experimental questions that require simultaneous imaging from two widely spaced cell  
18   layers in *Drosophila*<sup>21</sup>, sea slugs<sup>5, 6</sup> and other organisms. The optical system can be  
19   assembled from conventional optic parts and devices. In our implementation, we used

1 microscope parts from Olympus, but an equivalent system could now be constructed  
2 using, e.g., Thorlabs CERNA parts.

3 By combining our microscope with next-generation voltage-sensitive dyes  
4 (VF2.1(OMe).H<sup>13</sup>, we achieved simultaneous large-scale neuronal recording from two  
5 widely spaced cell layers at single-cell resolution, capturing not only action potentials but  
6 also small excitatory and inhibitory synaptic potentials. A primary feature of the system is  
7 its ability to acquire these signals at high speed, and without delay for image capture  
8 between the two focal planes. At present, this cannot be achieved by wide-brain  
9 volumetric Ca<sup>2+</sup> imaging as previously established for *C. elegans*<sup>2,3</sup>. With our newly  
10 developed microscope, we simultaneously recorded, for the first time, the activity of the  
11 majority of neurons in a leech ganglion. While beyond the scope of this study, the fact  
12 that VSD recordings contain both spikes and postsynaptic potentials makes it possible to  
13 infer network connectivity among the different individual, identifiable cells. This offers a  
14 notable advantage over techniques that only give access to spike events or intracellular  
15 Ca<sup>2+</sup> concentration.

16 The leech has 21 nearly identical segmental ganglia containing approximately  
17 400 neurons that are arranged in a highly conserved geometry<sup>12</sup>. For 148 of these neurons,  
18 functional descriptions have been published. (A gateway to the relevant literature is  
19 available online, at <http://www.danielwagenaar.net/ganglion>.) The ganglionic neurons  
20 are distributed in a single layer on the surface of the ganglion, but this layer wraps around  
21 both the dorsal and ventral sides, so that at best half of the neurons can be simultaneously

1 imaged with conventional microscopy. Our double-sided microscope, in contrast, has  
2 access to all of them, although surface curvature means that not all neurons can  
3 simultaneously be in sharp focus (Fig. 1b). A single light source was sufficient for  
4 illuminating both top and bottom surfaces, because the leech nervous system is  
5 sufficiently translucent to permit even lighting onto both sides.

6 In many leech ganglionic neurons, the somata exhibit both action potentials and  
7 synaptic potentials not greatly attenuated from their origin in the neuropil, a notable  
8 difference from typical monopolar neurons in invertebrate central nervous systems<sup>12</sup>.  
9 Hence, a low-noise imaging system using sensitive voltage sensors potentially enables us  
10 to analyze synaptic integration even in small neurons in the leech. In addition, our  
11 double-sided microscope is compatible with both intra- and extracellular electrode  
12 placement, enabling detailed electrophysiological interrogation of selected specific  
13 neurons along with optical imaging from the population.

14 Intriguing features that we observed using our pan-neuronal imaging system  
15 are (1) widespread distribution of neurons that are differentially involved in left and right  
16 ventral local bending (Fig. 3c, d), and (2) involvement in multiple behaviors of a large  
17 fraction of identifiable neurons (Fig. 4i, j).

18 With respect to (1), we found that not only the local bend interneurons and the  
19 motor neurons previously reported<sup>17</sup> discriminate between the stimuli, but so did many  
20 other neurons that had not previously been implicated in local bending. It has long been

1 known that the neural mechanism of local bending involves population coding<sup>22-27</sup>, but its  
 2 exact algorithm and computation remain unknown. Although the calculation of  
 3 discriminability here was based on stimulus category ( $P_V^L$  vs.  $P_V^R$ ) instead of actual local  
 4 bend patterns in the leech's body wall, the population dynamics of the highly  
 5 discriminative cells we identified putatively underlie the neuronal computation. The  
 6 discriminability maps from our study can thus be utilized for future investigations of  
 7 mechanosensory information processing.

8           With respect to (2), we observed that 43% of identifiable neurons on the ventral  
 9 and dorsal surfaces were involved in at least two of the three behaviors tested (local  
 10 bending, swimming, and crawling). This result indicates that the neural circuits for those  
 11 behaviors share many components while generating unique motor patterns for each  
 12 behavior. The percentage of circuit components shared between swimming and crawling  
 13 identified in this study differed from previous work<sup>9</sup>; in particular, the number of cells we  
 14 identified as involved in crawling (56) was lower than in the previous study (188). The  
 15 reason is probably that crawl episodes in our experiments were somewhat shorter  
 16 (typically only 3–4 cycles) than in the older study, resulting in a weaker coherence signal.  
 17 Double-sided imaging revealed a previously unappreciated difference between the swim  
 18 rhythm and local bending: The cell assemblies that are simultaneously active in the  
 19 former span both sides of the ganglion, whereas in local bending, they are mostly  
 20 confined to either the dorsal or the ventral side.

1           In this study, we identified imaged cells with known neurons using a  
2   semi-automatic mapping algorithm based on cell size and location along with an expert's  
3   assessment based on the physiological properties of cells along with this geometrical  
4   information. To gain more insight into the neuronal networks responsible for behavior, it  
5   will be necessary to carry out more accurate neurocartography, which we will achieve by  
6   combining functional mapping using machine learning methods<sup>10</sup> with a connectomic  
7   approach using serial block face scanning electron microscopy<sup>11</sup>. The combination of  
8   those techniques with double-sided VSD imaging will pave the way for future  
9   investigations on how the activity of all neurons in a central nervous system is recruited to  
10   process sensory information and to generate distinctive behaviors from overlapping  
11   neuronal circuits.

# 1    **Materials and Methods**

## 2    *Optical recording by double-sided microscope*

3            We acquired fluorescence images simultaneously from two focal planes using a  
4    custom double-sided microscope consisting of the fluorescence train of an upright  
5    microscope (Olympus BX, Tokyo, Japan) mounted on top of an inversed microscope  
6    (Olympus IX). The top microscope was used to image the upper focal plane while the  
7    bottom microscope imaged the lower focal plane. We used a 20x, 1.0 numerical aperture  
8    (NA), water-immersion objective for the upright and a 20x, 0.7 NA objective with  
9    cover-slip adjustment collar for the inverted microscope (both Olympus). The alignment  
10   of those two objectives was fine-adjusted manually so that cameras attached to the top  
11   and bottom microscopes saw the same field of view to within about 300 nm when the two  
12   focal planes were at the same depth.

13           The two objectives served as condenser for each other, so that blue excitation  
14   light delivered through the top objective for epifluorescence imaging also served as a  
15   transfluorescence light source for the bottom objective. Further, a red LED illuminator  
16   attached to the bottom microscope provided wide-field transillumination that enabled us  
17   to use the upright objective to visualize intracellular electrodes. Both objectives were  
18   mounted on standard turrets so that they could be rotated out of the way to make place for  
19   5x objectives used to visualize extracellular suction electrodes.

1           For VSD imaging, we used excitation light (bandpass filtered to  $470 \pm 15$  nm)  
2   from a high-power blue LED (LedEngin LZ1-10B200) controlled with optical  
3   stabilization<sup>13</sup>. In both the upright and inverted microscopes, we used a 490-nm dichroic  
4   mirror and 505-nm LP emission filter. Images were acquired with two cooled CCD  
5   cameras (QuantEM 512SC; Photometrics, Tucson, AZ) at a resolution of 512 x 128 pixels.  
6   The frame rate was set depending on which behavior was recorded: for local bending and  
7   swimming, images were acquired at 50 Hz; for crawling, images were acquired at 20 Hz.  
8   Imaging data were acquired using custom software VScope<sup>28</sup>. Optical and electrical  
9   recordings were synchronized by connecting frame timing signals from each camera to a  
10   data acquisition board that also recorded electrophysiology signals (see below).

11           VSD imaging is highly sensitive to even sub-micrometer motions. Because  
12   VSDs are located in cell membranes rather than the cytosol, a movement of less than 1%  
13   of a cell diameter can cause a signal change of well over 1% due to bright edge pixels  
14   moving out of a pre-defined region of interest (ROI). Since typical VSD signals are  
15   themselves far less than 1%, this can cause dramatic motion artifacts. To mitigate this  
16   problem, we replaced cooling fans inside each CCD camera with external blowers, since  
17   we determined that internal fans in cameras caused significant vibrations of the  
18   microscope objectives relative to the sample. After removing these fans, the noise in  
19   image sequences was dominated by shot noise.

# 1 *Animal maintenance and sample preparation*

2 Medicinal leeches (*Hirudo verbana*) were obtained from Niagara Leeches  
3 (Niagara Falls, NY) and maintained in artificial pond water at 15 °C. In experiments  
4 where only local bending was the target behavior, we dissected out short chains of  
5 ganglia from segments 8 through 12. In experiments involving swimming or crawling, we  
6 isolated whole nerve cords (Supplementary Fig 5), including the head brain, all 21  
7 segmental ganglia, and the tail brain. In all cases, the blood sinus surrounding the nervous  
8 system was dissected away around segmental ganglion 10. We removed the sheath from  
9 the ventral and dorsal surface of this ganglion before applying voltage-sensitive dyes. To  
10 induce swimming, a dorsal posterior (DP) nerve root in one of ganglia 11 through 13 was  
11 stimulated through a suction electrode. Brief electrical pulses (3 ms) were delivered at 50  
12 Hz in a 3-s-long train, with an amplitude of 7–8 V. To elicit crawling, several nerves from  
13 the tail brain were stimulated using the same stimulus parameters as for DP nerve  
14 stimulation. Isolated leech ganglia can move slightly move because muscle cells are  
15 embedding in the nerve cord. We therefore stabilized the ganglion to be imaged by tightly  
16 pinning down blood sinus tissue to the PDMS (Sylgard 184, Dow Corning, Midland, MI)  
17 substrate and by sandwiching adjacent connectives between small pieces of medical  
18 dressing (Tegaderm, 3M, Maplewood, MN) which was also pinned down, to minimize  
19 any motion artifacts. Throughout the dissection and during imaging, preparations were  
20 maintained in chambers filled with cold leech saline consisting of the following (in mM):  
21 115 NaCl, 4 KCl, 1.8 CaCl<sub>2</sub>, 2 MgCl<sub>2</sub>, 10 glucose, and 10 HEPES, at pH 7.4. Only before

1 crawling was induced, we temporarily replaced the cold saline with room temperature  
2 (20–23 °C) saline to obtain the most natural crawling rhythm. We bath loaded 800  $\mu$ M  
3 VF2.1(OMe).H<sup>13</sup> (provided by Evan Miller) in leech saline containing 1% Pluronic acid  
4 (Powerload<sup>TM</sup> Concentrate 100x, Thermo Fisher Scientific, Waltham, MA). To help  
5 with dye penetration into the cell membranes, we circulated the solution using a pair of  
6 peristaltic pumps (approximately 1.1 mL/min flow rate) with outflows directed at the  
7 dorsal and ventral surfaces of the ganglion, for 20 minutes total.

8

## 9 *Electrophysiology*

10 We recorded intracellularly from up to three neurons simultaneously using  
11 20–50 M $\Omega$  glass microelectrodes filled with 3 M potassium acetate and 60 mM potassium  
12 chloride, using Neuroprobe amplifiers (Model 1600; A-M systems, Sequim, WA).  
13 Intracellular recordings provided additional information regarding the behavioral state of  
14 the preparation as well as confirmation of the corresponding optical signals. We recorded  
15 extracellularly using suction electrodes and a four-channel differential amplifier (Model  
16 1700; A-M Systems). All electrical signals were digitized at 10 kHz using a 16-bit  
17 analog-to-digital board (NI USB-6221; National Instruments, Austin, TX) and VScope  
18 software<sup>28</sup>.

1

## 2 *Basic data processing*

3           We outlined the images of individual cell bodies manually as regions of interest  
4 using VScope. Pixel values within each cellular outline were then averaged in each frame,  
5 yielding a raw fluorescence signal. Signals were processed to remove artifacts from  
6 micromotion (next section), and to correct for slow reduction of overall fluorescence  
7 intensity due to dye bleaching. The latter was achieved by subtracting locally fitted  
8 third-order polynomials using the SALPA algorithm<sup>15</sup> with a time constant of 1 to 15 s. In  
9 addition, brightness averaged across the areas of the ganglion outside of ROIs was  
10 subtracted for each frame to reduce global noise due to fluorescent crosstalk among top  
11 and bottom images<sup>16</sup>. Finally, signals were normalized to their average value and  
12 expressed as a percent change in fluorescence ( $\Delta F/F$ ).

13

## 14 *Motion correction*

15           As mentioned above, motion artifacts were reduced by removing fans from  
16 CCD cameras and by pinning down ganglia tightly on the PDMS substrate. However,  
17 even very small motions can cause highly detrimental artifacts in VSD recordings.

18           To correct for small motions, we designated the middle frame of any recording as a  
19 reference frame, and generated a pair of artificial frames by shifting the reference frame

one pixel to the left or to the right. Let  $\mathbf{I}_R$  and  $\mathbf{I}_L$  be vectors consisting of the intensity values of the pixels in the right- and left-shifted reference frames, and let  $\mathbf{I}'$  be the intensity vector of an arbitrary frame in the recording. As long as the motion is small (less than or approximately equal to one pixel),

$$\Delta x = 2 (\mathbf{I}' - \mathbf{I}_L) \cdot (\mathbf{I}_R - \mathbf{I}_L) / \|\mathbf{I}_R - \mathbf{I}_L\|^2 - 1,$$

where  $\cdot$  is the vector product and  $\|\mathbf{I}\|$  is the vector norm, is a good estimate for the motion in the x-direction between the frame under study and the reference frame. (The reason is that an image shifted by  $\Delta x$  pixels can be approximated as

$$\mathbf{I}' = [(1 - \Delta x) \mathbf{I}_L + (1 + \Delta x) \mathbf{I}_R] / 2,$$

as long as  $|\Delta x| \ll 1$ . The first equation is derived from the second by minimizing with respect to  $\Delta x$ .)

The same method can of course be used for motion in the y-direction. More interestingly, the method can be used for other affine distortions as well. For instance, if we calculate artificial frames by rotating the reference frame by  $\pm 0.1^\circ$ , the above procedure would yield estimates of image rotation (in units of  $0.1^\circ$ ).

Using this method, we estimated and corrected for small motions that may occur with the preparation or even due to vibrations in the microscope, thus preventing motion artifacts in the extracted VSD traces (Supplemental Figure 2).

1

## 2 *Calculation of prediction success*

3           In our experiments on the encoding of stimulus identity by individual neurons,  
 4 we performed 10 trials stimulating the left P<sub>V</sub> cell and 10 stimulating the right P<sub>V</sub> cell, in  
 5 order (LR)(RL)(LR)(RL)... To calculate how well each cell “predicted” the stimulus  
 6 identity (i.e., “left” or “right”), we calculated the average  $\Delta F/F$  during the first 0.5 s of  
 7 each stimulus relative to the preceding reference phase, separately for each trial. Taking  
 8 each trial in turn, we then took that trial and its “partner” trial out, and calculated the  
 9 average  $\Delta F/F$  for the 9 “left” stimuli out of the remaining 18 trials and also for the “right”  
 10 stimuli. The “partner” trial was the next trial for odd-numbered trials, and the preceding  
 11 trial for even-numbered trials. If the  $\Delta F/F$  in the trial under consideration was closer to the  
 12 average  $\Delta F/F$  of the “left” trials in the training set than to the average of the “right” trials,  
 13 the neuron was considered correct in its “prediction” of stimulus identity if the trial under  
 14 consideration was in fact a “left” trial, and conversely for “right” trials. The percentage of  
 15 trials in which a cell correctly predicted stimulus identity in this sense was used as a  
 16 measure of prediction success. Any cell that correctly predicted stimulus identity in at  
 17 least 75% of trials (50% being chance performance) was considered to encode stimulus  
 18 identity.

1

## 2 *Coherence analysis*

3           We used multitaper spectral analysis<sup>29</sup> to estimate the coherence between  
4 optical signals from individual cells with a common reference. That reference was the  
5 stimulus train for local bending, the optical signal of a DI-1 motor neuron for swimming,  
6 or the intracellular electrode signal of an AE motor neuron for crawling. For each  
7 recording, we calculated the 95% confidence interval for the magnitude of estimated  
8 coherence under the null hypothesis that a signal was not coherent with the reference<sup>30</sup>. A  
9 cell was considered to be involved in the behavior expressed during a given trial if its  
10 measured coherence exceeded this confidence interval.

11

## 12 *Canonical mapping*

13           The overall layout of neurons within leech ganglia is highly conserved between  
14 ganglia within an animal as well as between animals, but the precise geometry does vary.  
15 In order to identify cells seen in the VSD image sequence (Supplementary Fig.5a) with  
16 neurons in the canonical map, we developed a graphical user interface that allows us to  
17 proceed as follows. First, we mark all the visible cells as regions of interest on the image  
18 (Supplementary Fig.5b). Then, we overlay the canonical map over this (Supplementary  
19 Fig.5c). To the trained eye, the identification of many of the larger cells is immediately

1 obvious, so we register these identities (using a drag-and-drop mechanism in the GUI;  
2 (Supplementary Fig.5d)). This partial mapping of ROIs to identified neurons allows the  
3 program to do a coarse alignment between the canonical map and the actual image using  
4 affine transformations local to each of the four packets of cells (Supplementary Fig.5e).  
5 (The ganglion is divided by giant glial cells into several packets<sup>12</sup>, the boundaries of  
6 which are indicated on the canonical map.) This preliminary alignment enables us to  
7 identify several other neurons with high confidence, after which the computer can  
8 perform a local alignment step. Finally, the computer assigns putative identities to the  
9 remaining ROIs, leading to a nearly complete mapping between ROIs (orange dots in  
10 Supplementary Fig.5f) and identified neurons (cross marks).

11

## 12 *Determination of which cells are consistently involved in a behavior*

13 For each neuron in each animal, we determined whether its coherence exceeded  
14 the 95% confidence interval of the null hypothesis that a given neuron was not involved  
15 in a given behavior. If a neuron exceeded that threshold for a given behavior in four out of  
16 six animals, it was considered to be involved in that behavior (Fig. 4i.) Since swimming  
17 and crawling are both symmetric behaviors, we included both members of a homologous  
18 pair if (and only if) at least one member exceeded the 97.5% C.I.

19

# 1     *Clustering and calculation of integration coefficients*

2             We clustered cells based on the matrix of the correlation coefficients of their  
3     activity patterns, separately for each behavior (by constructing a dendrogram based on the  
4     correlation distance followed by tree cutting). We then assigned a dorsoventrality index  
5     (DVI) to each cell, which was equal to the fraction of dorsally located cells in that cell's  
6     cluster. This is what is shown in the histograms of Fig. 5b. Cells in clusters with fewer  
7     than three members were ignored for this calculation; the results did not change  
8     qualitatively if this threshold was changed to two or five. Based on the DVI, we  
9     calculated the integration coefficient (CI) of Fig. 5c as:

$$10 \quad CI = \langle 1 - 2 |DVI - 1/2| \rangle,$$

11     where  $|\cdot|$  denotes absolute value and  $\langle \cdot \rangle$  denotes the average across all cells (except those  
12     not in clusters of size three or more).

13

# 14     *Software for data analysis*

15             All data processing and statistical analysis were performed in GNU Octave,  
16     version 4.0.0.
